Abstract

Mesoporous alumina has been successfully synthesized from bauxite residues (red mud) as raw material and cetyltrimethylammonium bromide (CTAB) as template at room temperature. The effects of crystallization time and molar ratio of H₂O/CTAB on structural and textural properties of mesoporous alumina were investigated. The synthesized product was characterized by XRD, FTIR, SEM-EDX, TEM, N₂ adsorption-desorption and acidity test using pyridine adsorption. The XRD pattern and SEM micrograph showed that the synthesized product possessed an amorphous phase and irregular shapes. From obtained results, it could be observed that crystallization time and H₂O/CTAB ratio influenced the surface acidity of mesoporous alumina.

INTRODUCTION

Red mud is a waste material or residue derived from the alumina (Al₂O₃) production from bauxite. The Al₂O₃ production uses Bayer Process in which sodium hydroxide (NaOH) is added to produce Al₂O₃ from bauxite, as well as solid residue called red mud (Kumar, 2015). In average, 1-1.5 tons of red mud may be generated after producing 1 ton of alumina (Brunori et al., 2005). Red mud is comprised from some metal oxides such as iron oxides, silicon oxides and undissolved alumina with a wide range that depended on the ore used (Snars and Gilkes, 2009). The concentration of alumina in red mud is about 25-30% (Liang, 2014). Therefore, red mud can be used as an alumina source to synthesize alumina-based materials.

Alumina has been applied as catalyst, ceramic, catalyst support, conductor and strengthener in composite because of its uniform channels, good thermal conductivity, high Lewis acidity and high specific area (Xia et al., 2003). Red mud from Bintan has been successfully used as raw material to synthesize a mesoporous alumina by adding CTAB as template at room temperature using sol-gel method. Mesoporous alumina from Bintan's red mud confirmed to have a mesoporous structure with BET surface area of 241 m²/g and pore size of 3.820 nm with ratio CTAB/Al of 0.32 as optimal ratio (Ramdhani et al., 2018).

Sol-gel method is an easy yet cheap method to synthesize mesoporous alumina. Some parameters such as time and water content can be used to optimize the synthesis process. It has been reported that the synthesized product with longer time of aging has bigger particle size (Rousseaux et al., 2002). Water content is proven to give effects

on the particle size, crystallinity and specific area of synthesized product (Isley and Penn, 2008).

Here, the synthesis of mesoporous alumina using red mud from Bintan as alumina source and CTAB as template was conducted in room temperature. The effects of crystallization time and molar ratio of H₂O/CTAB on surface acidity of the synthesized product were studied.

EXPERIMENTAL

Materials

The starting materials, the powders of red mud were obtained from Bintan Island of Indonesia, cetyltrimethylammonium bromide (CTAB, Merck, 99%), sodium hydroxide (NaOH, Merck, 99%), hydrochloric acid (HCl, SAP, 37%) and deionized water were used in this study. The chemical composition of Bintan's red mud was shown in Table I.

Preparation of precursor

The process of extraction and synthesis were adopted from Ramdhani et al. (2018). Red mud was leached with HCl 6N solution (solid/liquid ratio 1:5 g/mL) at 90 °C under stirring for 2 h, and then filtered and washed with deionized water. The leachate was collected as aluminum source. Then NaOH 5 N solution was dropped into filtrate under stirring. The NaAlO₂ was filtered to separate the precipitate of impurities (Fe³⁺, Ca²⁺, etc). HCl 6 N was added to the solution with stirring until the precipitate was completely formed. The

precipitate was used as alumina source in synthesis of mesoporous alumina.

Table 1 Chemical composition analysis by XRF for red mud.

Chemical composition	Mass %
Fe ₂ O ₃	49.87
Al ₂ O ₃	31.39
SiO ₂	15.03
TiO ₂	1.57
P ₂ O ₅	0.56
K ₂ O	0.54
CaO	0.15
Cr ₂ O ₃	0.10

Synthesis of mesoporous alumina from red mud

The precipitate from previous steps was mixed with CTAB and water with molar ratio H₂O/CTAB of 600, 800, 1012, 1200 and 1400. The mixture was stirred for 1 h for all samples and then aged for 72 h at room temperature. The final product was recovered by filtration, washed with deionized water and dried at 120 °C for 24 h. The dried product was calcined at 550 °C for 6 h. The effect of crystallization time was studied with molar ratio H₂O/CTAB = 1012. The mixture was stirred for 1 h for all samples and then aged for 3, 12, 24, 48 and 72 h at room temperature. The final product was recovered by filtration, washed with deionized water and dried at 120 °C for 24 h. The dried product was calcined at 550 °C for 6 h. The general method (molar ratio H₂O/CTAB 1012 and aging time 72 h) was adopted from Ramdhani *et al.* (2018). The synthesized sample with variation of crystallization time was labeled as AMA-(crystallization time, h.) for example AMA-24, while sample synthesized with variation of H₂O/CTAB molar ratio was labeled as AMH-(molar ratio of H₂O/CTAB) for example AMH-1200.

Characterization of mesoporous alumina

X-ray powder diffraction patterns of the samples were recorded on a Philips Expert with Cu K_α (40kV, 30 mA) radiation in the range 2θ = 5-50°. The infrared spectra (wavenumber range 400-1400 cm⁻¹) of characteristic vibration bands were monitored by FTIR Shimadzu Instrument Spectrum One 8400S. The specific surface area and pore size distribution were determined from N₂ adsorption-desorption using a Quantachrome Instruments Nova 1200. SEM images and elemental analysis were recorded using Zeiss EVO MA 10 instrument. TEM images were recorded using Hitachi TEM HT7700.

The surface acidity of mesoporous alumina synthesized from red mud was measured by pyridine adsorption using FTIR spectrometer. Calcined samples were pressed into a pellet and then placed in homemade glass transmission cell and outgassed at 400 °C for 4 h under N₂ flow. The pyridine was adsorbed at room temperature for 1 h. Subsequently, the sample was purged under N₂ flow at 150 °C for 3 h. The infrared spectra (range 1300-1800 cm⁻¹) of characteristic vibration band were recorded by FTIR spectrometer.

RESULTS AND DISCUSSION

Synthesis of mesoporous alumina from red mud

Mesoporous alumina has been synthesized from Bintan's red mud with sol-gel method. There were some steps involved to prepare the precursor since red mud contained other compounds aside Al₂O₃ such as Fe₂O₃ and SiO₂. The preparation has two steps. The first one was the removal of SiO₂ by adding acid, while the second one was the removal of Fe₂O₃ by adding base. This procedure has been successfully done by Pan *et al.* (2013) to obtain alumina from coal kaolin and Ramdhani *et al.* (2018) to obtain alumina from Bintan's red mud. Precipitate alumina was formed after adding acid into filtrate from removal Fe₂O₃ process, in which aluminum hydroxide precipitate would form completely in pH ~7 (Pan *et al.*, 2013). This precipitate

was used as precursor in synthesis of mesoporous alumina. Fig 1 shows the SEM image and EDX graph for each step in preparation of precursor. As observed from SEM images in Fig 1, all of the residues have an irregular shape and size. According to EDX graph, residue from SiO₂ removal (RSD1) and Fe₂O₃ removal (RSD2) still contained aluminum. This finding was caused by unfinished washing step in each process. Therefore, the residue still contained aluminum. Otherwise, the alumina precipitate (GM-AL) didn't contain any Si or Fe elements which indicated that this process was good enough to obtain alumina from Bintan's red mud.

Alumina salt from previous steps was used as alumina source in synthesis of mesoporous alumina. The mass ratio of CTABr and alumina salt used was 1.57, as reported by Ramdhani *et al.* (2018). The water content inside the alumina salt has been calculated by comparing mass of the salt before and after drying. Alumina salt from the previous steps contained 93.97% of water content that could predict the mass of product to be low. This wet precipitate was added into CTAB solution under stirring for 1 h. The purpose of using wet precipitate was to facilitate the distribution of alumina inside the solution (Ramdhani *et al.*, 2018). The solution was aged for 3, 12, 24, 48 and 72 h. This variation was used to optimize the polymerization process of Al-O-Al so the product would possess stable structure (Moatti *et al.*, 2014). The removal of CTAB was done by calcination at 550 °C for 6 h. There were three steps of CTAB decomposition i.e. ammonia removal at 200-320 °C, structural decomposition of CTAB at 320 °C and removal of the remaining CTAB from alumina structure to form a pore at 395 °C (Liu *et al.*, 2007). Solid product after calcination process was collected. The mass of the product was shown in Table 2. According to Table 2, the mass of product was increased for longer crystallization time. It could be concluded that the effectiveness of polymerization process could be increased for 72 h of crystallization time, as reported by Pan *et al.* (2013) and Ramdhani *et al.* (2018). Sample AMA-72 has the highest mass, due to the synthesis of mesoporous alumina with certain H₂O/CTAB molar ratio at crystallization time for 72 h.

Wang and Ying (1999) have reported that the higher ratio of H₂O could help the hydrolysis process and interfere the particle growth at the same time. Li et al. (2004) also confirmed that the higher amount of H₂O in synthesis process, the hydrolysis and polycondensation processes also got faster so the mass of the product could be increased. In this study, the mass of synthesized product was tended to increase with increasing of the molar ratio of H₂O/CTAB. The mass of product with variation of H₂O/CTAB molar ratio was shown in Table 3.

Characterization of mesoporous alumina from red mud

XRD pattern of fresh red mud was shown in Fig. 2. As observed, the Bintan's red mud contained some minerals such as hematite (Fe₂O₃), goethite (FeOOH), gibbsite (Al(OH)₃), boehmite (γ-AlO(OH)), anatase (TiO₂) and quartz (SiO₂). This result was confirmed by the elemental analysis of Bintan's red mud with XRF technique (Table 1). The XRD pattern of red mud has a similar pattern as reported by Liang et al. (2014), Sushil and Batra (2012), and Ghosh et al. (2010).

Fig. 2 XRD pattern of red mud.

Fig. 3 and Fig. 4 show the XRD pattern of mesoporous alumina from red mud with variation of crystallization time and H₂O/CTAB molar ratio after calcination at 550 °C for 6 h. There was no characteristic peak detected in XRD pattern for all samples. The absence of the characteristic peak indicated that the material has bimodal porous with amorphous wall (Pan et al., 2013). According to Cheng et al. (1995), when synthesis has been done with concentration of CTAB under 40%, the synthesized product has irregular mesopore. Therefore, no peak was detected for all of the samples.

The samples of red mud, as-synthesized alumina, and calcined alumina were investigated by infrared spectroscopy (Fig. 5). Infrared spectra for all calcined samples showed similar spectra, i.e. peak at around 3450 and 1635 cm⁻¹ for stretching and bending vibrations of O-H groups, and also at 729 and 590 cm⁻¹ for Al-O vibration. Similar

infrared spectra were stated by Pan et al. (2013). In addition, there was no sharp peak at around 1200-1000 cm⁻¹ characteristic for stretching vibration of Si-O (Qoniah et al., 2015), which only appeared in red mud sample. This finding concluded that the solid sample only consisted of alumina. Meanwhile, infrared spectra of as-synthesized sample only showed a peak at around 1400 cm⁻¹, characteristic for bending vibration of -CH₂ and -CH₃ from cetyltrimethylammonium (Yue et al., 2010). The absence of this peak in all infrared spectra of calcined product indicated that cetyltrimethylammonium was completely removed from the solid product.

The N₂ adsorption-desorption isotherms of the synthesized-alumina from red mud has been carried out to determine the specific surface area, pore size distribution and pore volume of the synthesized materials (Fig. 6). The N₂ adsorption-desorption isotherm for sample AMA-24 showed hysteresis at p/p₀ = 0.4-0.9, indicating that the sample has isotherm type IV. According to the isotherm type by IUPAC, it was confirmed that the synthesized-alumina from red mud contained mesopore. The isotherm adsorption for AMH-1200 also indicated the type IV isotherm based on the presence of H3 hysteresis loop. According to IUPAC classification, the hysteresis loops for AMA-24 and AMH-1200 were apparently composite of H1 and H3 type hysteresis loops, indicating the samples to consist of a plate-like particles and slit-like pores. The type of hysteresis confirmed that the synthesized product has a mesopore and synthesized sample from a clay usually has slit like pores. The pore structure parameters were calculated according to the mathematical models from the N₂ adsorption-desorption. The data were given in Table 4. According to BJH calculation, AMA-24 has 132.122 m²/g mesoporous surface area with pore size of 3.831 nm and AMH-1200 has 184.474 m²/g mesoporous surface area with pore size of 3.833 nm. The pore size distribution for AMA-24 and AMH-1200 were shown at Fig. 7. This result showed the similar profiles as reported by Ramdhani *et al.* (2018) with a larger mesoporous surface area. It was interesting to note that AMA-24 and AMH-1200 also have microporous structure since they have pretty high adsorption in p/p₀ < 0.3. The BET calculation showed that the microporous surface area for AMA-24 and AMH-1200 were 212.485 m²/g and 168.311 m²/g, respectively. The pore volume for AMA-24 and AMH-1200 were 0.426 cc/g and 0.363 cc/g.

The morphology and the elemental analysis of the alumina samples were investigated with SEM-EDX. Morphologies of mesoporous alumina synthesized with variation of crystallization times were shown in Fig. 8. The particle size and the formation of mesoporous aggregates were controlled by the reaction condition, such as time, pH and addition of structure directing agent (Petushkov *et al.*, 2011). In this study, the size and shape for all samples were irregular without any particular differences. Meanwhile, morphology of the mesoporous alumina samples synthesized with variation of $H_2O/CTAB$ molar ratios were shown in Fig. 9. The obtained result was similar with the result for variation of time. There was no significant difference in the particle size reported by Isley and Penn (2008). It might be caused by the precursors that did not have regular shape to start off. The EDX graph showed peak for bromine for AMA-72 and AMH-1200 samples. The peak for bromine might appear due to unfinished washing procedure, causing the ions to stay still inside the pore even though calcination was already done.

AMA-72 was investigated with TEM to monitor the morphology of the product as shown in Fig. 10. As observed, AMA-72 has morphology of both wormlike structure (Fig. 10 a and b) and thin sheet-like structure (Fig. 10 c and d). In this paper, alumina was synthesized from wet precipitate alumina salt. The water content in the alumina salt was pretty high. Huang *et al.* (2014) reported that the molar ratio of H_2O/Al from the precursor could give an impact to the morphology of the synthesized product. When the water content was increased, the Boehmite plates would get larger and have thin sheet-like structure. It was confirmed that mesoporous alumina from red mud has an excess water content. The wormlike structure from AMA-72 was a characteristic structure from alumina that synthesized by adding surfactant (de Llobet *et al.* 2013). The porous structure of alumina (Fig. 10 (a) and (b)) resulted the formation of irregular pores. Beck *et al.* (1992) reported that molar ratio of surfactant and aluminum < 1 would make hexagonal surfactant system with a regular pore structure. It might be different case since the surfactant used in this study was CTAB. According to Cheng *et al.* (1995), when synthesis has been done with concentration of CTAB $< 40\%$, the synthesized product would exhibit irregular mesopore. Since the mass ratio of CTAB and alumina salt was 1.57, it could be understood that the concentration of CTAB inside the precursor was way below 40% so the product would be expected to possess an irregular pores and shape. These findings also have been reported by Ramdhani *et al.* (2018). The dark part from the AMA-72 showed the close packed of

platelets created by random stacking of nano-platelets. The higher water content from precursor, the tighter agglomeration was formed (Huang *et al.*, 2014). We predicted that the slit-like pore that was seen from hysteresis loop (Fig. 6) resulted from this randomly stacked of nano-platelets.

Fig 10. TEM images of AMA-72.

Acidity study

Alumina is one of the solids that has a strong Lewis acid site (Parry, 1963). In this study, the synthesized product was tested using pyridine to identify the surface acidity. After pre-treatment using pyridine sorption, the product was characterized with FTIR and the results were showed in Fig. 11 and Fig. 12.

The infrared spectra showed peak in the range wavenumber of $1447-1440\text{ cm}^{-1}$ for all samples. This peak was identified as characteristic peak for Lewis acid that indicated interaction of pyridine and alumina acid sites (Platon and Thomson, 2003). The peak for Bronsted acid was not found in the wavenumber $\sim 1550\text{ cm}^{-1}$. This result showed that the product has Lewis acid sites on the surface but not Bronsted acid sites. We concluded that mesoporous alumina synthesized from red mud still has Lewis acid site even though not as strong as mesoporous alumina synthesized from commercial material. Therefore, mesoporous alumina has potential to be catalyst support for increasing surface area and Lewis acid sites of the catalyst.

Fig 12. Pyridine-FTIR Spectra of mesoporous alumina from red mud with variation of H₂O/CTAB molar ratio.

CONCLUSION

This study has been proved that bauxite residue (red mud) could be employed as alumina source for synthesis of mesoporous alumina with CTAB as template. The effects of crystallization time and H₂O/CTAB molar ratio were investigated and the obtained results showed the significant effects on mass of product and acidity of surface. Increasing time of synthesis and H₂O/CTAB molar ratio caused the increase in mass of product and presence of Lewis acid sites on the surface.
